Length Frequency Analysis of Pelagic Fish Species

CELESTE PHILBRICK

Introduction

The capture of small pelagic fish supports a considerable number of artisanal and commercial fishermen in the Philippines. In the province of Marinduque, the commercial fishery - which relies exclusively on ringnet vessels - depends upon stocks of small, juvenile Decapterus macrosoma, russelli, Rastrelliger kanagurta, Auxis thazard, Selar crumenophthalmus, Katsuwonus pelamis, Thunnus albacares, and T. obesus.

Specimens of these species were sampled around Marinduque to learn how their growth compares with estimates obtained from samples collected in other parts of the Philippines. The mean sizes of the major species captured by ringnets were also calculated. These were compared to the national mean for this gear type (BFAR 1986).

Methods

Length-frequency data were collected between October 1985 and August 1986 in the Tablas Strait-Tayabas Bay region of the Central Philippines. Sampling was carried out aboard a ten gross ton ringnet vessel one to three times per month. Mesh size in the bunt of the ringnet was 2.6 centimeters. The methods for deck sampling recommended by FAO (1980, 1981) were followed.

All species in the catch were noted. The ELEFAN programs (Pauly 1982, Ingles and Pauly 1984) were used to analyze some of the length frequency data that were collected.

Results and Discussion

The bulk of the catch consisted of the abovementioned species; incidental species were: Euthynus affinis, Megalaspis cordyla, Elagatis bipinnulata, Trichurus haumela, T. lepturus, Gnathodon speciosus, Sphyraena barracuda, S. obtusa, Rachycentron canadus, Scomberomorus commerson, Megalops cyprinoides, Tylosurus strongyurus, T. giganticus, Hemirhamphus far, Medepedalion breve, Sarda orientalis, Coryphaena hippurus, and Scomberoides commersonianus.

Mean lengths and length ranges of the dominant species in the catch are given in Table 1. The range of lengths of fishes caught in Marinduque is smaller than reported elsewhere, and this suggests that immature individuals from much of the catch in Marinduque. This is particularly obvious for Thunnus albacares and Auxis thazard.

This limited size range reduced the usefulness of length frequency data for growth estimations, and hence results for only two species are presented here.

The growth parameter estimates obtained for *Decapterus macrosoma* are $L_\infty = 26$ cm, $K = 1.0$, with mean length at first capture $L_c = 17.5$ cm and $M = 1.8$ year$^{-1}$ (Fig. 1). Annual recruitment appears to have occurred in one single pulse (Fig. 2); this matched the results obtained for this species by Ingles and Pauly (1984) and Corpuz et al (1985). The growth parameter estimates obtained for *Sellar crumenophthalmus* are $L_\infty = 26.5$ cm, $K = 1.25$. $L_c = 21.1$ cm and $M = 2.1$ year$^{-1}$. Annual recruitment of *S. crumenophthalmus* appears to occur in two pulses (Fig. 2). These estimates of growth, mortality and recruitment may be of utility in modelling fish populations for the purpose of fisheries management or may add to the knowledge on the life history of the three species. It is recommended, however, that an alternative method of aging be undertaken for comparative purposes.\(^{a}\)

\(^{a}\) Editor's note: several authors have had in the past problems with the estimation of growth parameters from length frequency data on *S. crumenophthalmus*, i.e., it was difficult to assess whether K was "high" (near 2 year$^{-1}$) or "low" (near 1 year$^{-1}$, as in the present case) (See also Dalzell, this issue).
